

Noxious effects
of the increasing eutrophication
of coastal marine ecosystems:
how far should we reduce
the terrestrial nutrient loading?

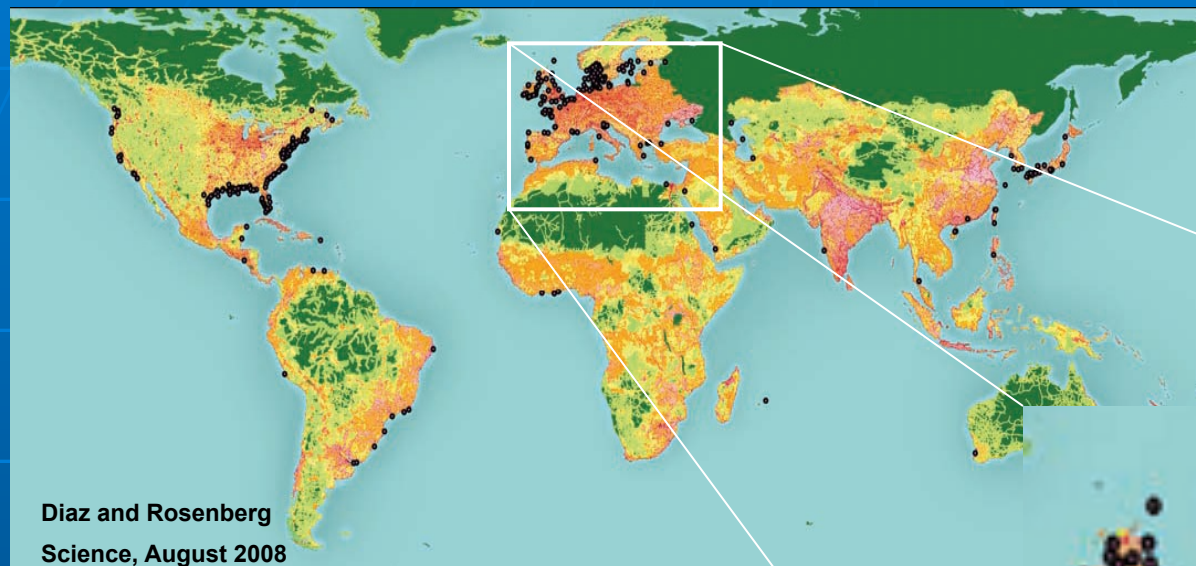

Alain Ménesquen
Ifremer/Brest

Contents

Eutrophication symptoms

The ultimate threat: the « dead zones »

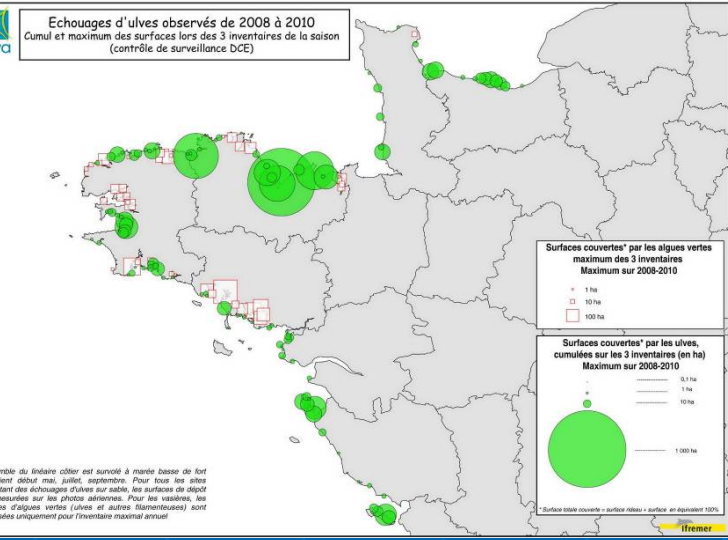

Hypoxia sites in the world

Hypoxia sites in Europe

- Baltic Sea
- Skagerrak, Kattegat
- North Sea
- British and French estuaries
- Northern Adriatic Sea and mediterranean lagoons
- Black Sea

Macroalgal proliferations « green tides »

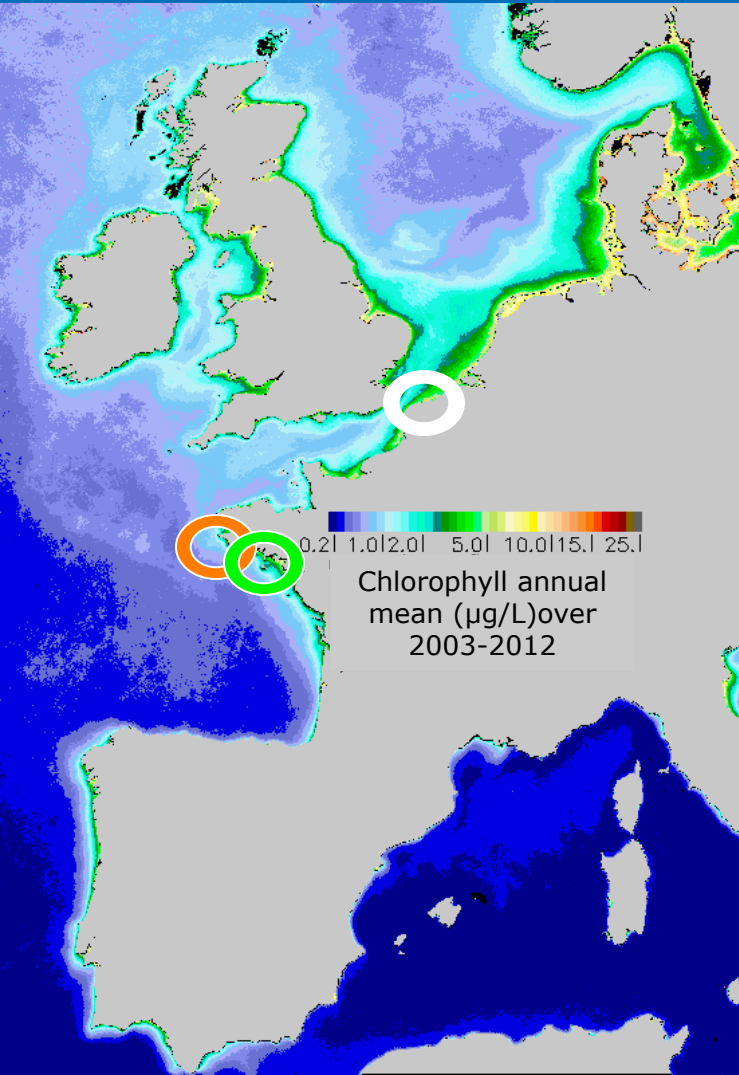

The most **visible** form of eutrophication is made by green algae accumulation in very shallow areas:

- ❑ bottom-fixed Enteromorpha in estuaries
- ❑ free-floating Ulva on sandy beaches

Phytoplanktonic proliferations « coloured waters »

Phaeocystis
Nord de la France

Noctiluca
Bretagne-sud 2004

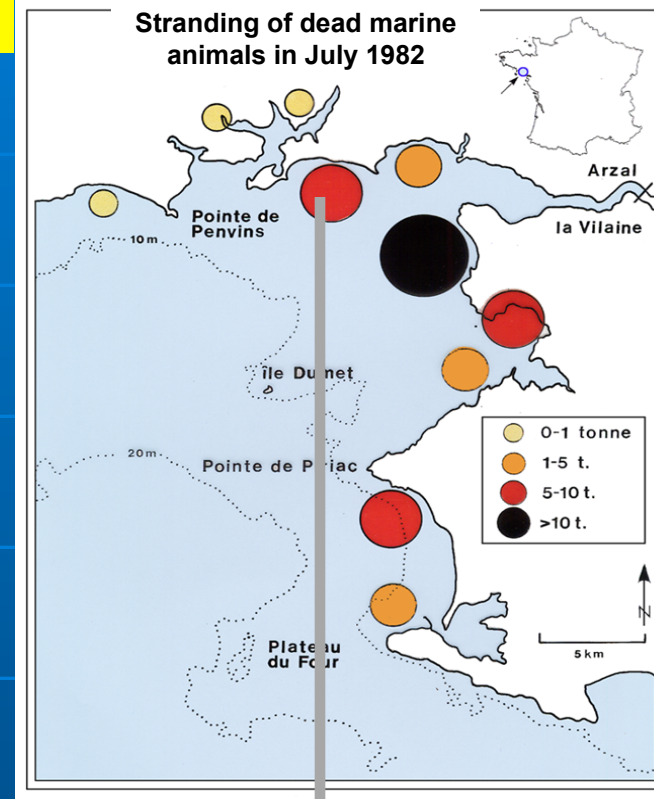

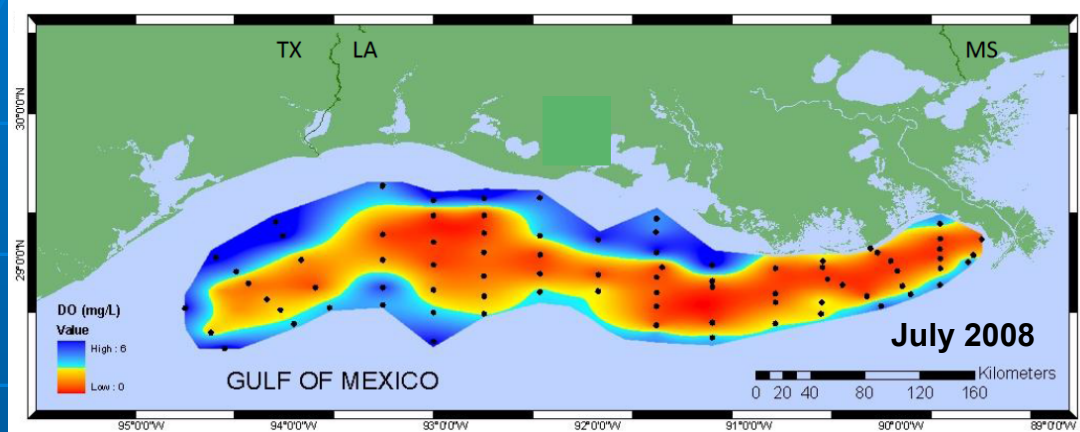

Lepidodinium
La Baule 2012

Hypoxic episodes

~ 200 km²

~ 20 000 km²

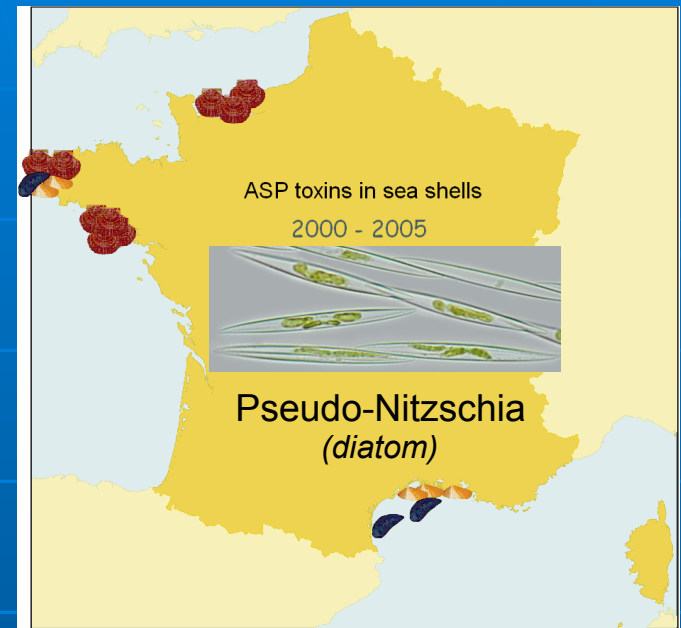

2008-2009 measurements by the MOLIT buoy in the Vilaine bay

The most harmful form of eutrophication for the ecosystem is made by coloured waters in the plumes of enriched rivers leading to hypoxia in bottom layer

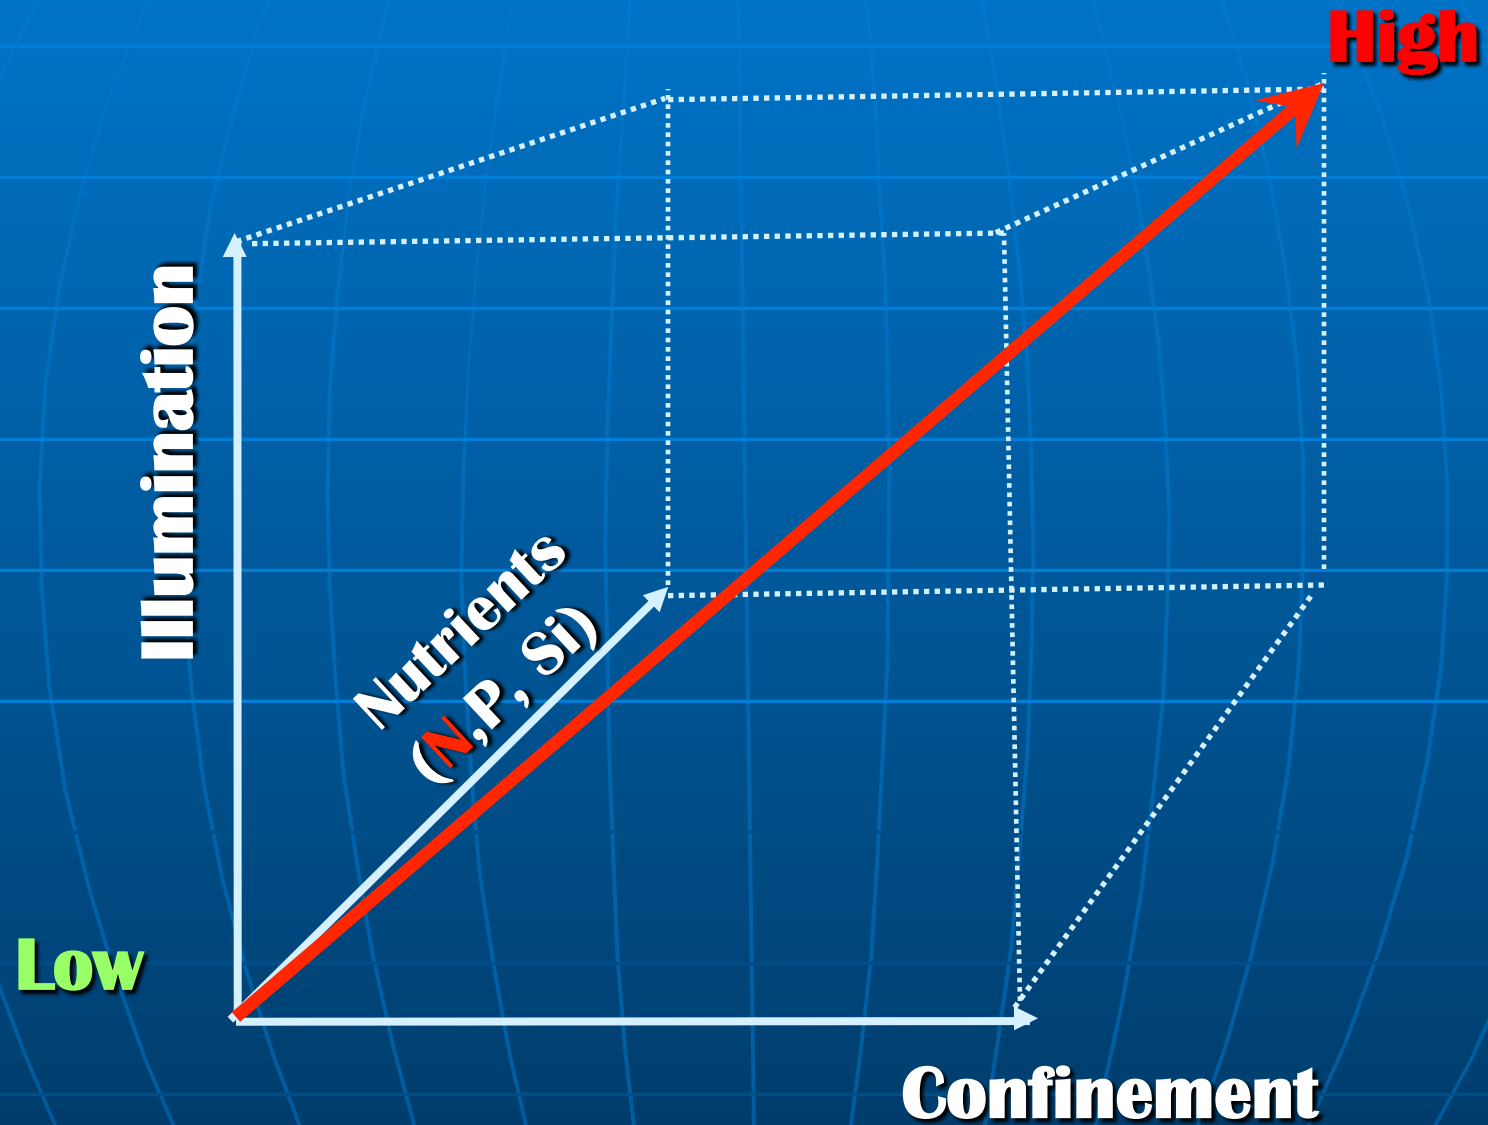

Toxic phytoplankton

The most **harmful** form of eutrophication **for the human consumer** is made by blooms of toxic phytoplanktonic species leading to **seashell contamination**. **N/P/Si increase enhances toxin production**

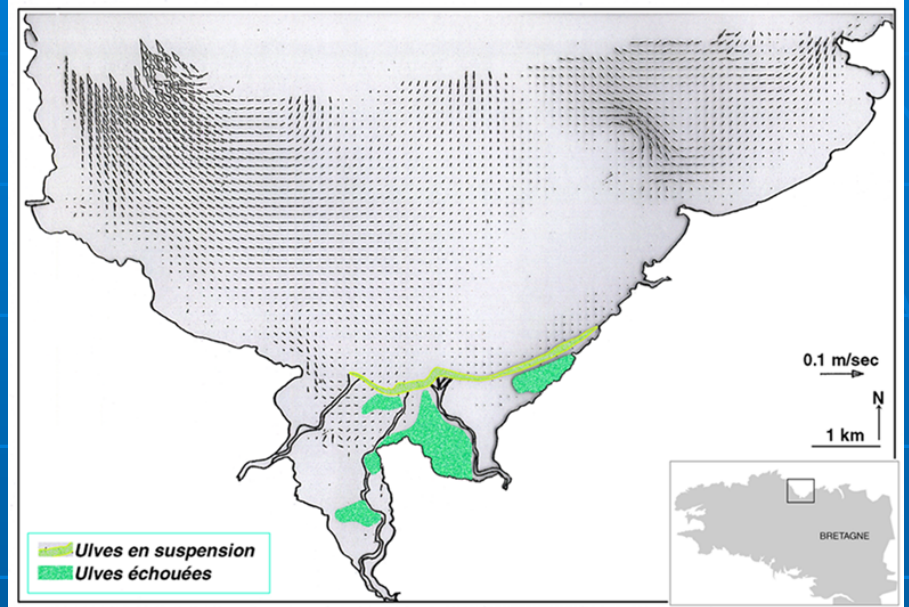

Main causes

The eutrophication tripod

Confinement

Horizontal weak residual currents

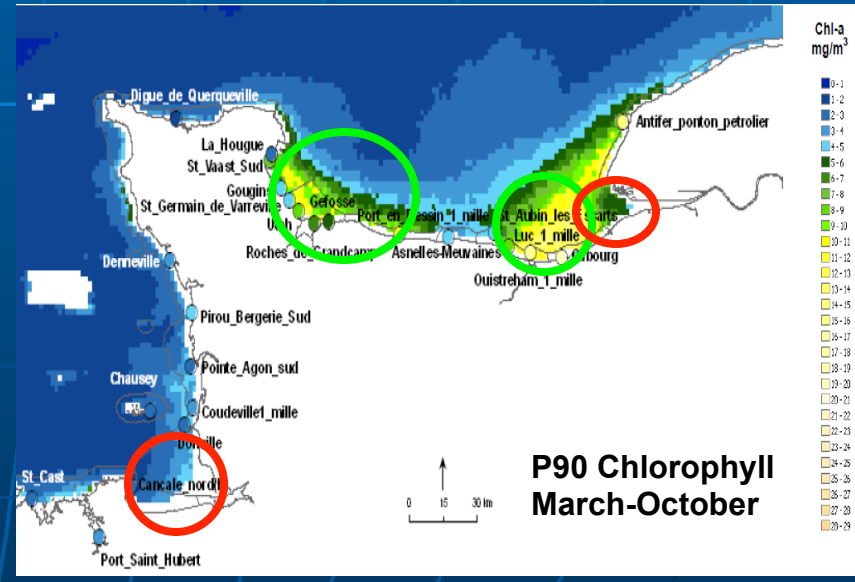

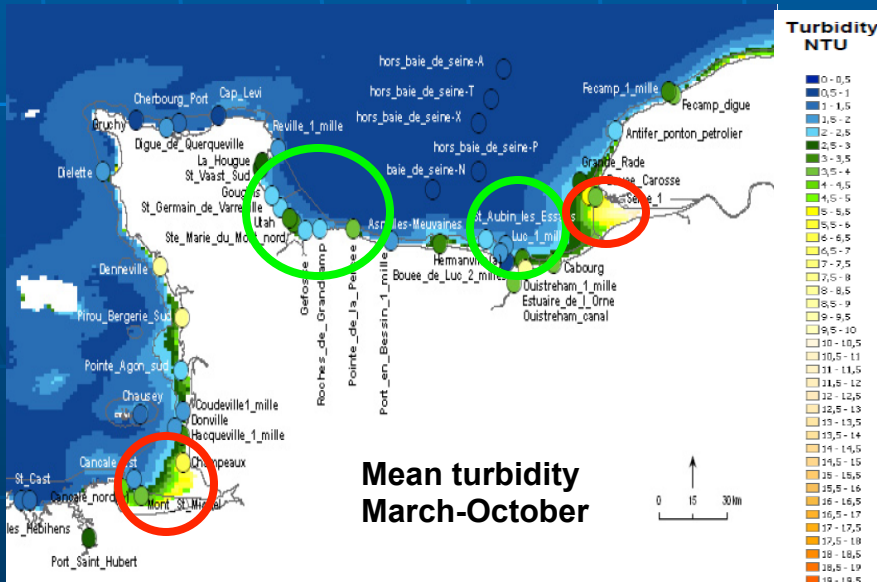

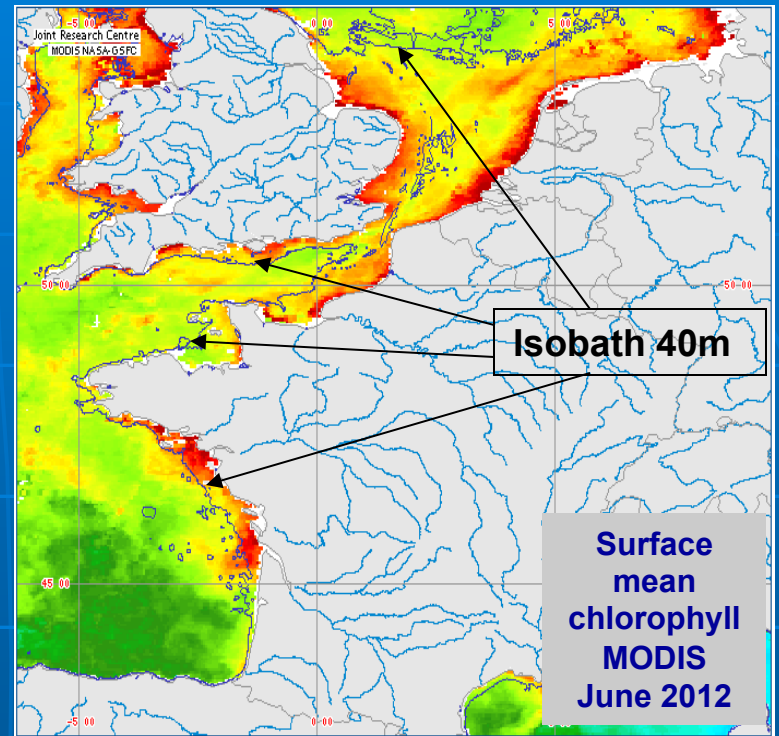

Vertical stratification

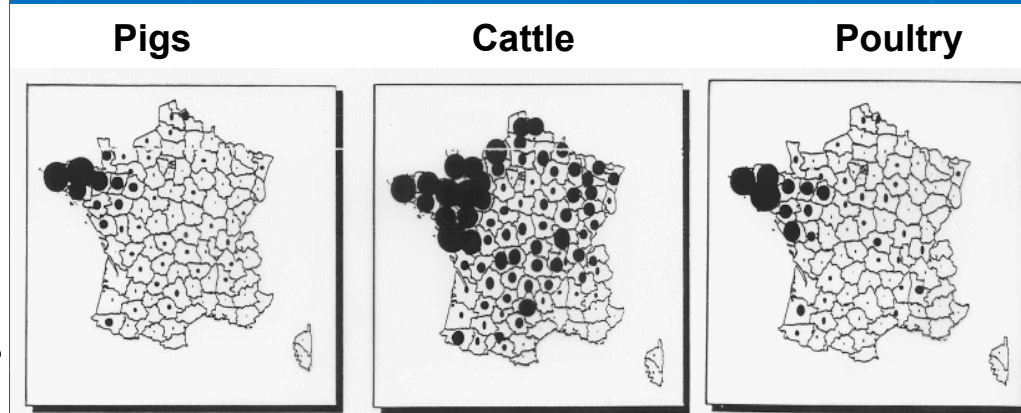

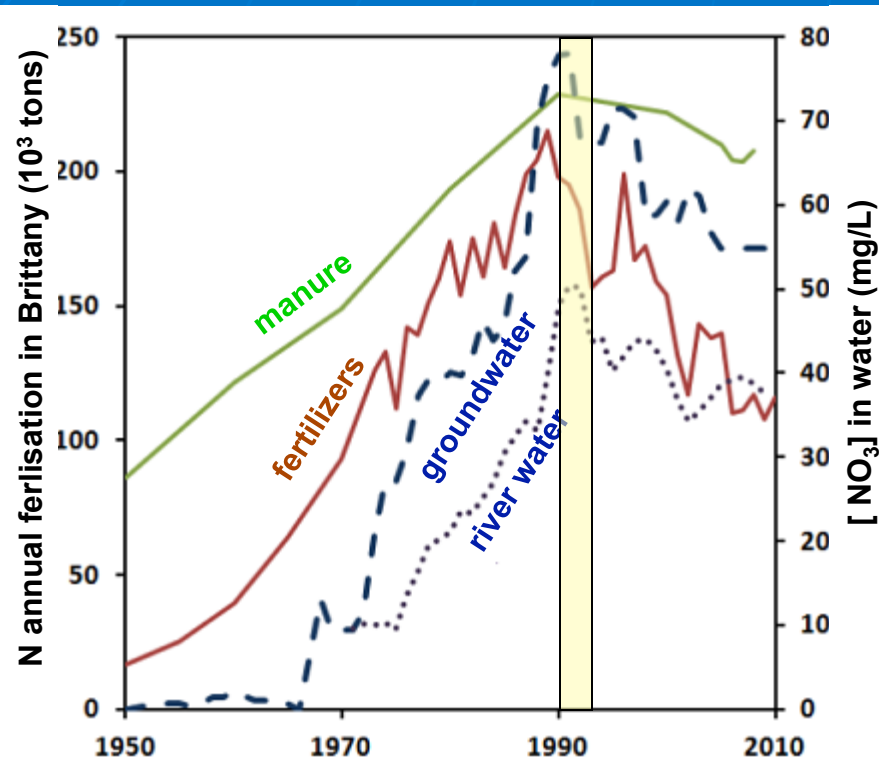

Illumination

Shallow waters

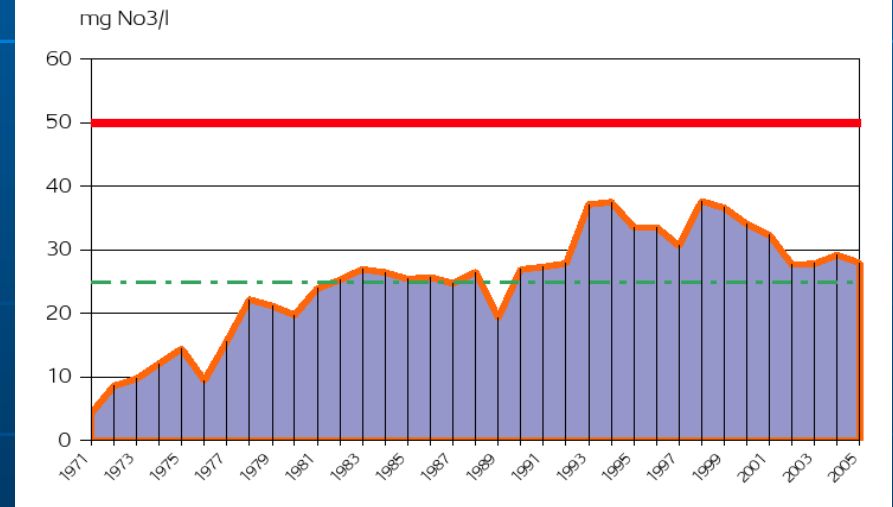

Clear waters

Nitrogen increase (case of Brittany)

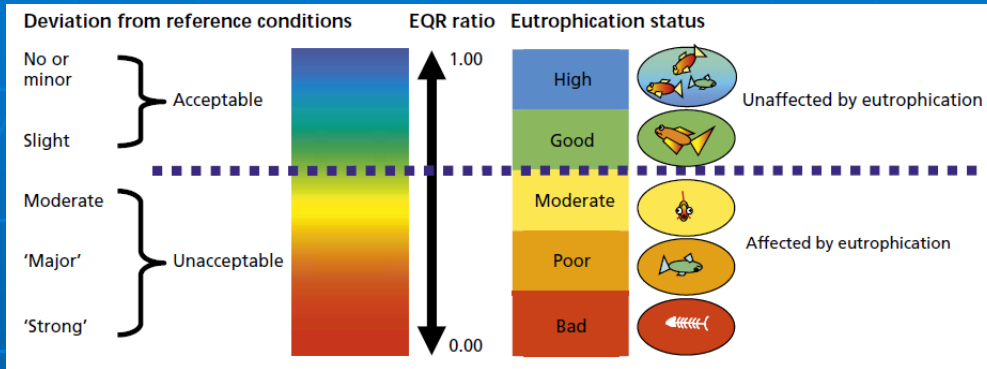

Annual mean of nitrate concentration in French Brittany rivers

Intensive livestock farming has increased land fertilization by a factor 10 during the 1960-1990 period

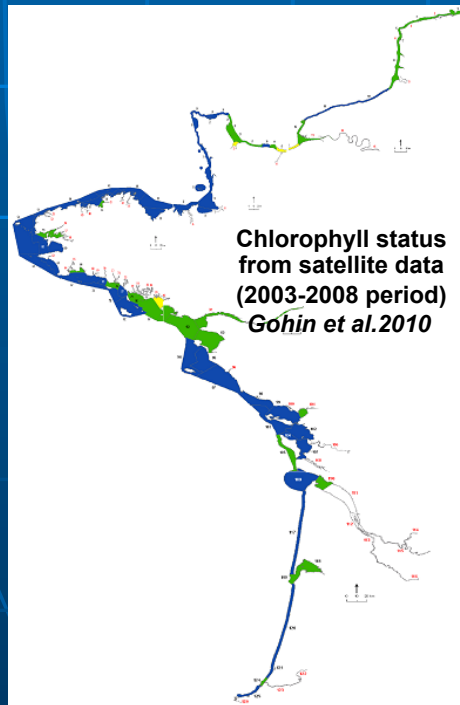

Management aspects

The European Directives point of view

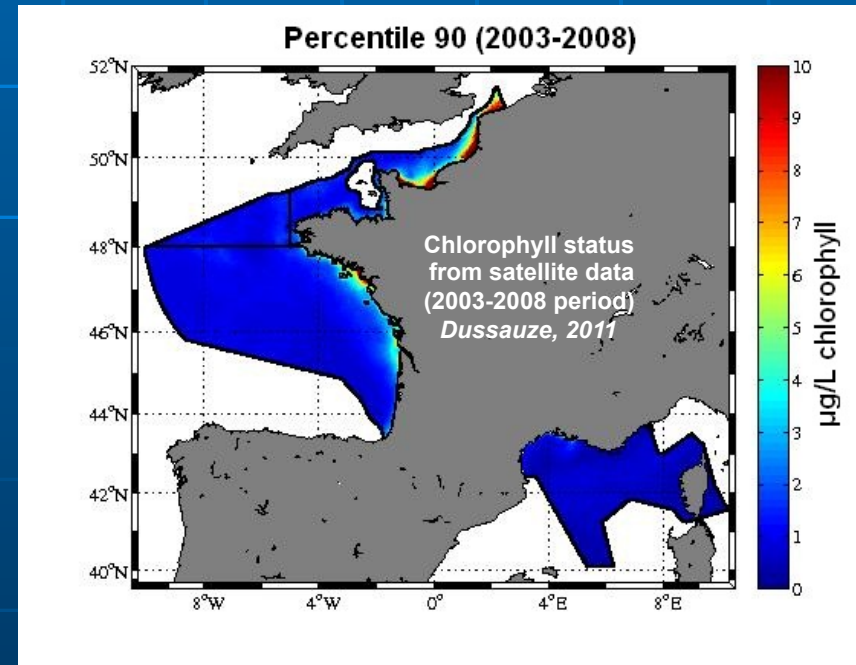

GES → **Good Environmental Status of the EU's marine waters by 2020**

Water Frame Directive (2000)
(for coastal water masses only)

Marine Strategy Framework Directive (2008)
(for continental shelf sub-regions)

But...

No legal threshold for marine nutrients !

For NO_3 , the 50mg/L maximum admissible concentration is only for drinkable freshwater ;

50 mg/L $\text{NO}_3 \approx 10$ times the freshwater pristine concentration

≈ 100 times the coastal marine pristine concentration !

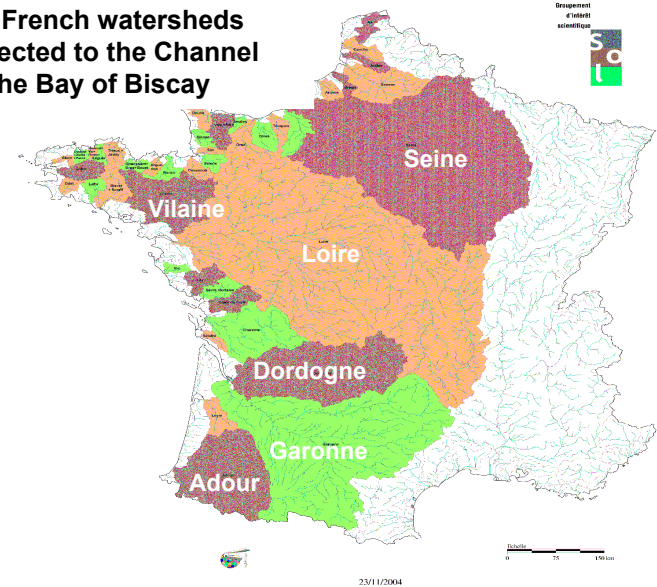

Various national thresholds for marine chlorophyll !

Percentile 90:

		
For France (Atlantic):	5 10 20 40	$\mu\text{g/L}$ chlorophyll
For UK:	10 15 20 25	$\mu\text{g/L}$ chlorophyll
For Spain (Biscay):	2 5 10 15	$\mu\text{g/L}$ chlorophyll

Many small watersheds and few big ones involved in coastal marine enrichment

Main French watersheds connected to the Channel and the Bay of Biscay

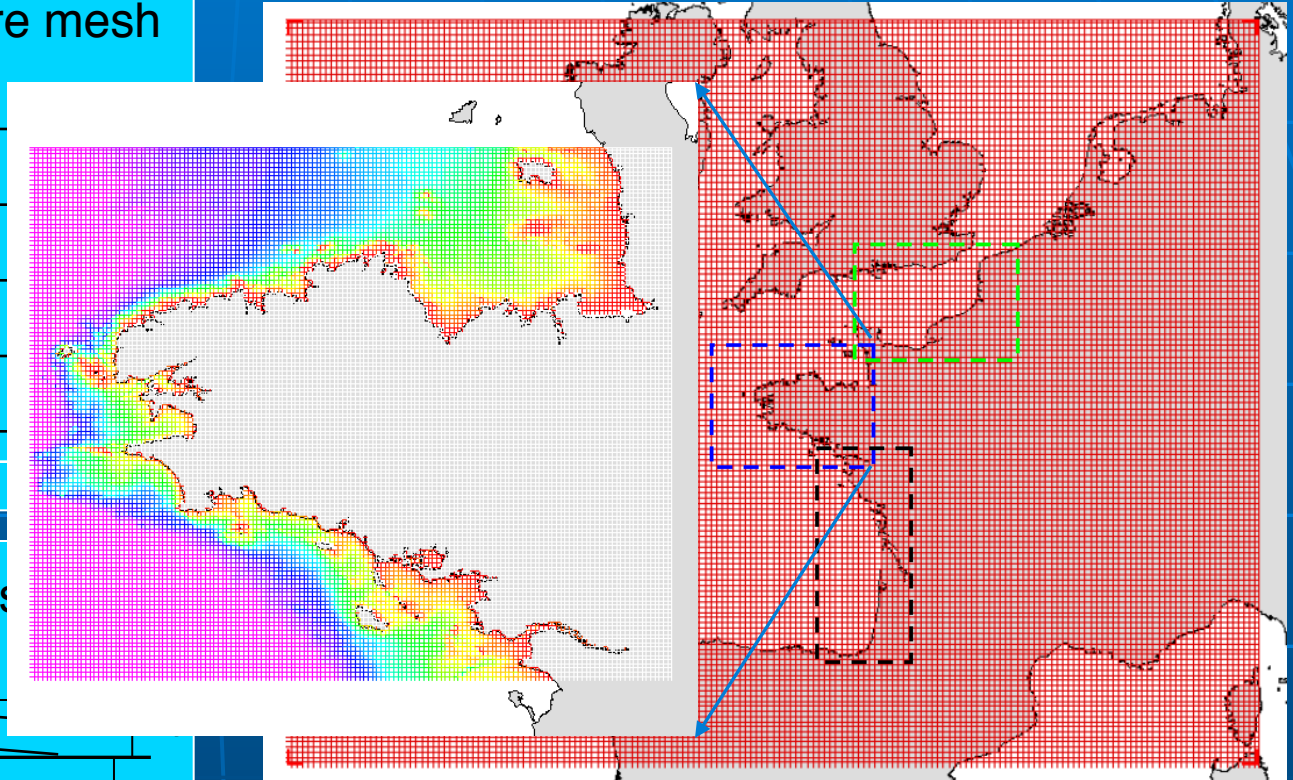

4 recurrent questions:

- What is the marine area influenced by each river?
- When several plumes merge in a coastal zone, what is the respective influence of each plume on the eutrophication?
- What would be the optimal nutrient reduction scenario for a given marine target?
- Can we provide real-time maps of risk for hypoxia or toxicity?

The modelling tool

The hydrodynamic MARS-3D model

NSEW regular grid, square mesh

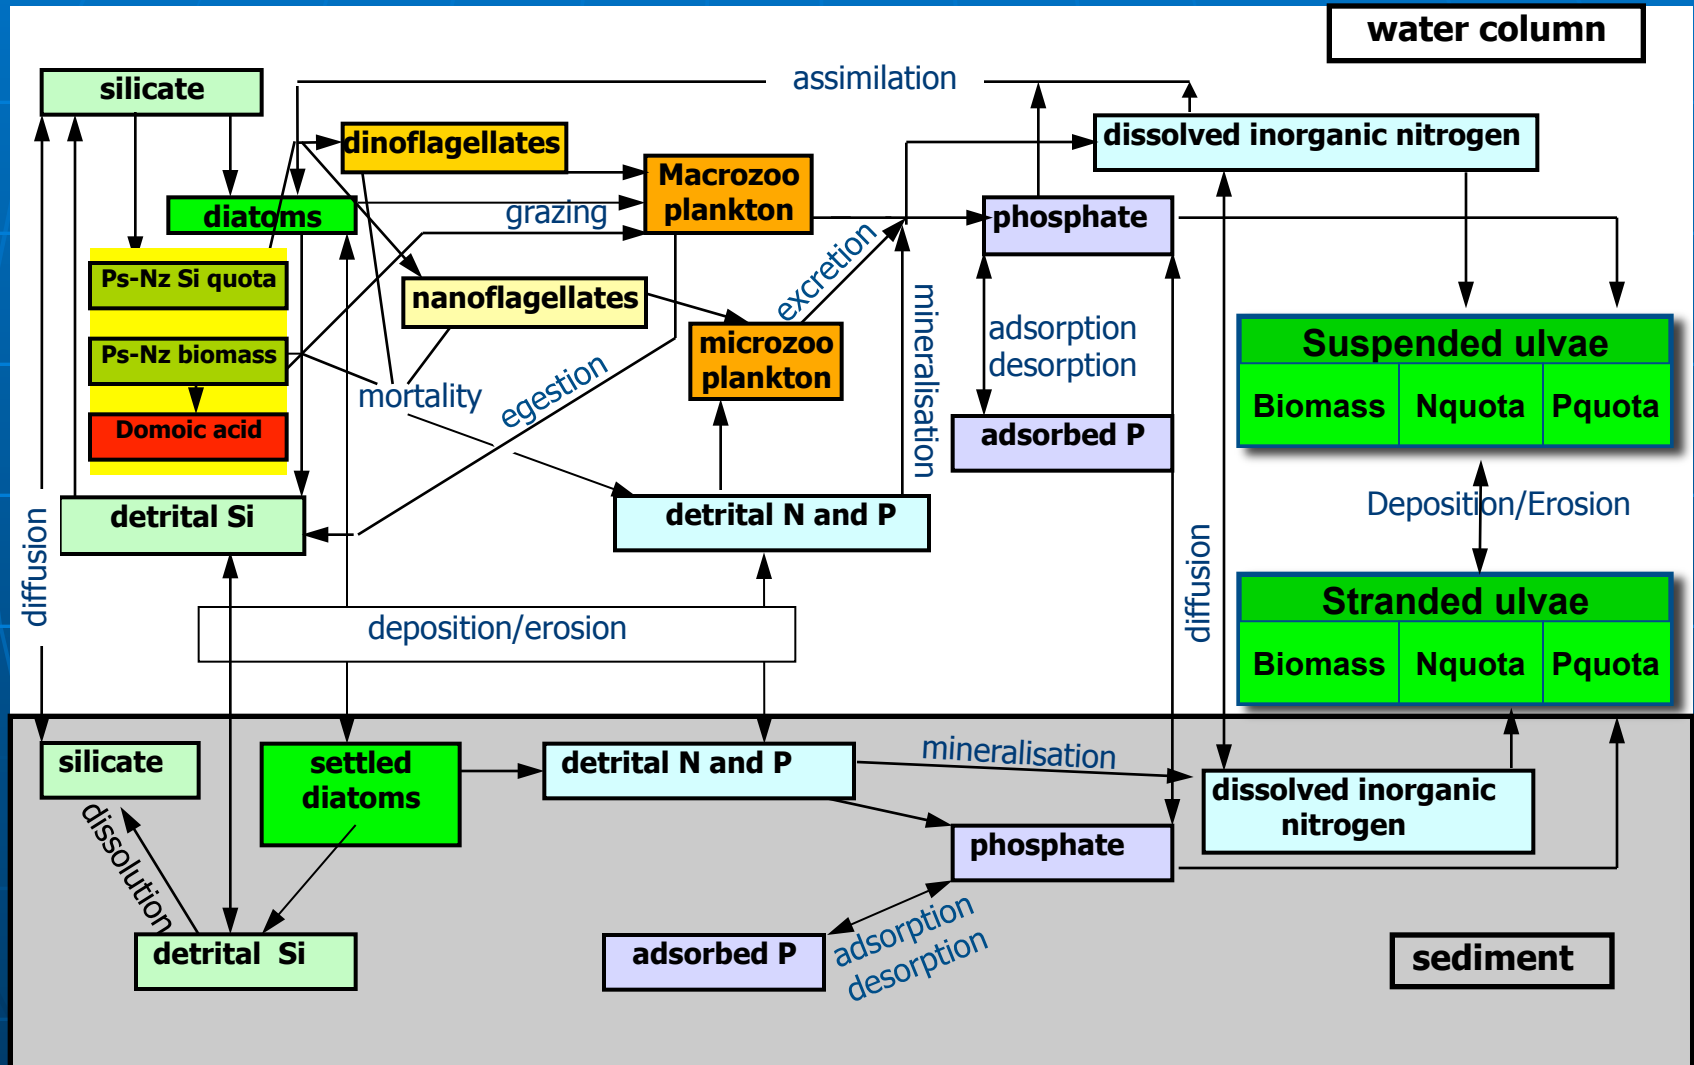

30 Relative σ -layers

Basic grid \rightarrow 4x4 km meshes
Grids for small plumes \rightarrow 1x1 km meshes

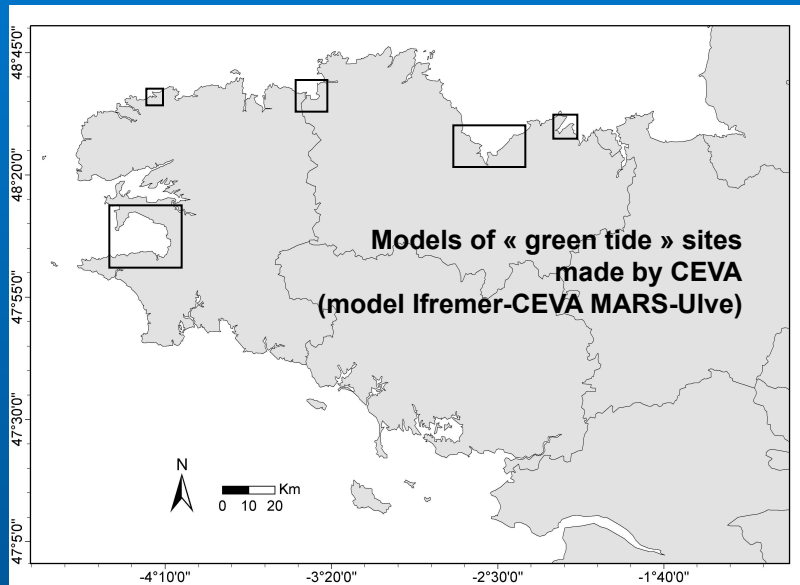

The biogeochemical model ECO-MARS3D

Off-line scenario results

1/ Case of on-shore « green tides »

Simulation of reduction scenarios of nitrate river loading

Measured coverage (ha)
and simulated biomass
(tons of fresh weight)

Fresnaye

Ulva nitrogen content
(%o dry weight)
measured and simulated

St Brieuc

Lannion

Guissény

Douarnenez

	Lannion 2005	Douarnenez 2005	St-Brieuc 2002	Guissény 2005	Fresnaye 2004
5 mg.t ⁻¹	69	77	54	71	74
10 mg.t ⁻¹	51	60	41	53	62
15 mg.t ⁻¹	36	44	30	41	51
20 mg.t ⁻¹	23	29		31	42
25 mg.t ⁻¹	13	15		25	31
30 mg.t ⁻¹	6	8		18	24

Simulated decrease (%) of the green tide
for various nitrate concentrations in rivers

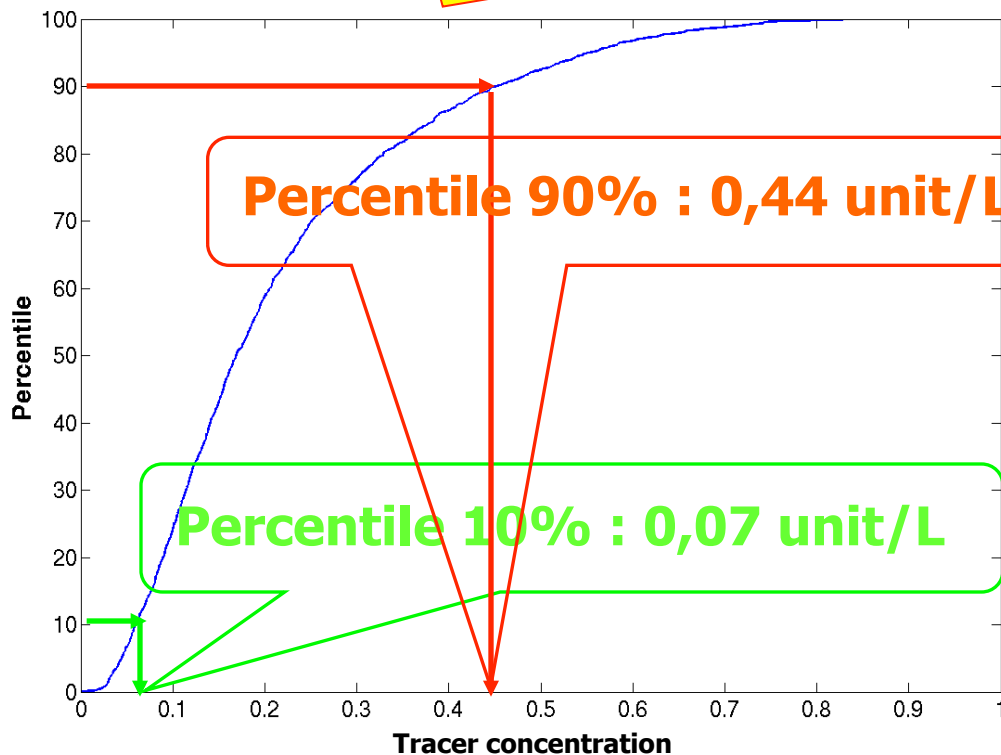

10mg/L NO₃ is necessary to halve the green tides

2/ Case of off-shore « coloured waters »

Computing the statistical region of influence of a river

- A conservative tracer is permanently forced to 1 in the river under study

- On a 10-year long run, the model provides 3650 daily tracer concentrations in every mesh

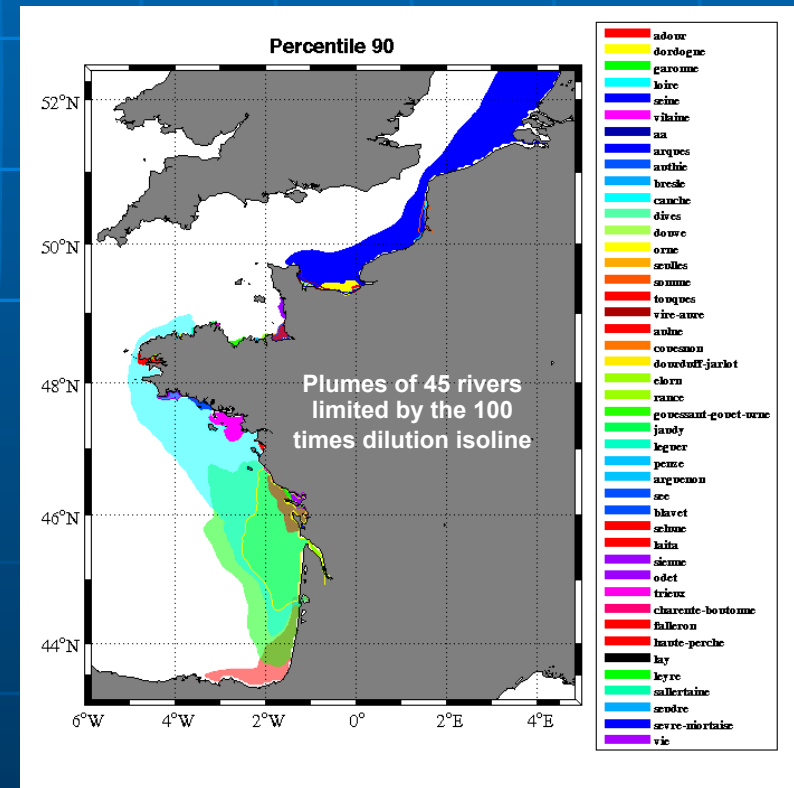

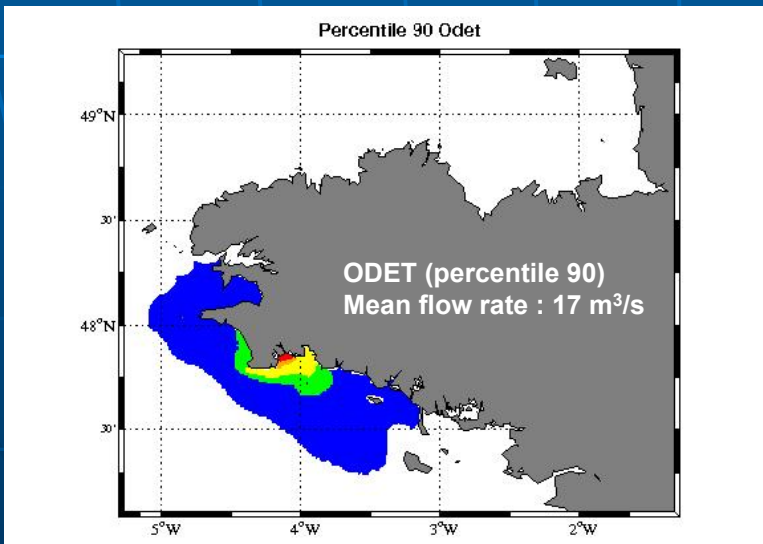

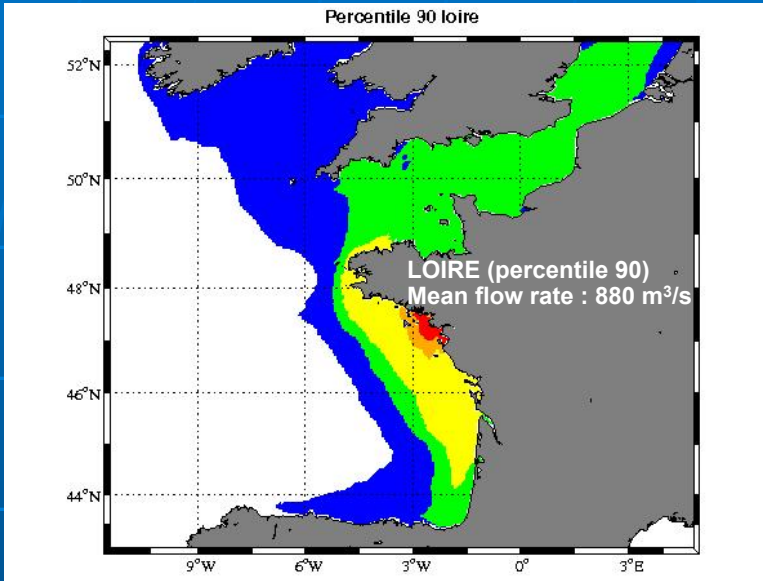

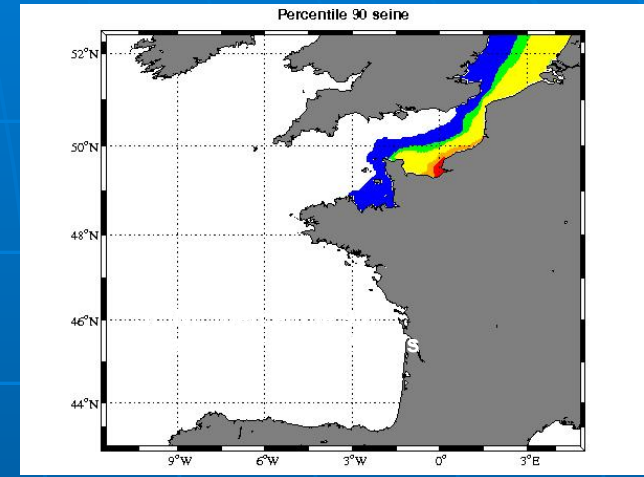

- In every mesh, the distribution function of these 3650 values can be computed

- Any percentile value can be deduced:
e.g. the median and the percentiles 10% and 90%

- A map can be drawn for any specific percentile

Some results along the Atlantic-Channel coast

Optimising global nitrate reduction

(ONEMA-Ifremer project)

Principle: In winter, nitrate is a conservative tracer

- Anywhere, marine nitrate concentration is a linear combination of diluted river loadings and oceanic background
- Linear optimization technique (Simplex) applies

Questions:

- Which is the Good Ecological Status marine level?

→ 15 $\mu\text{mol/L NO}_3$ or more ?

- Which is the price of a 1mg/L NO_3 reduction in a river?

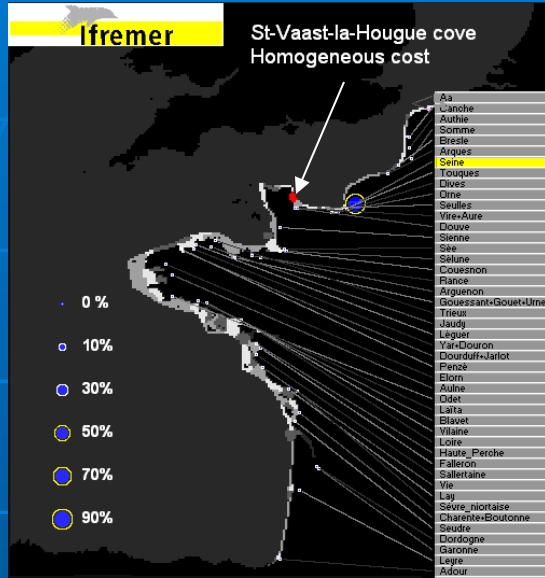

→ Homogeneous or Proportional to watershed area ?

- Which is the target area ?

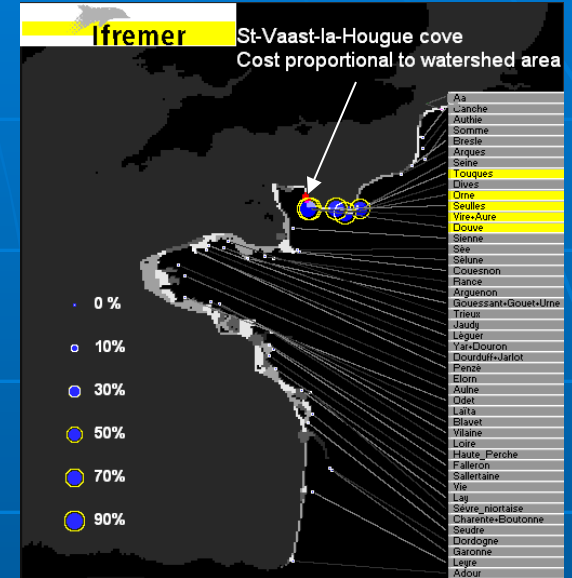

→
A single WFD mass ?
All the WFD masses together ?
A MSFD sub-region ?
A bathymetric stratum ?

Various optimised nitrate reductions

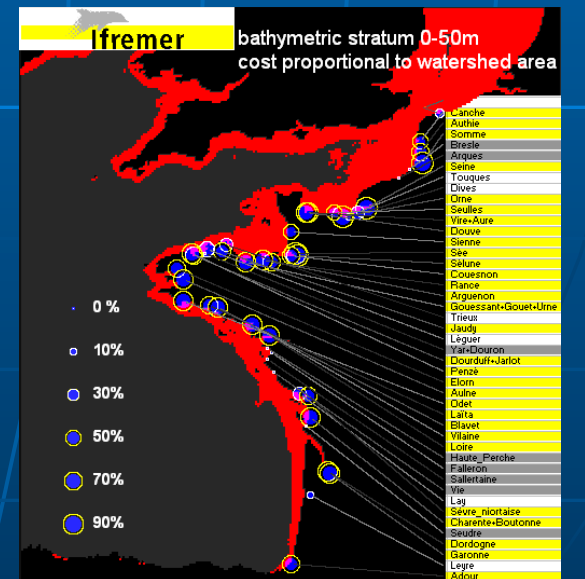

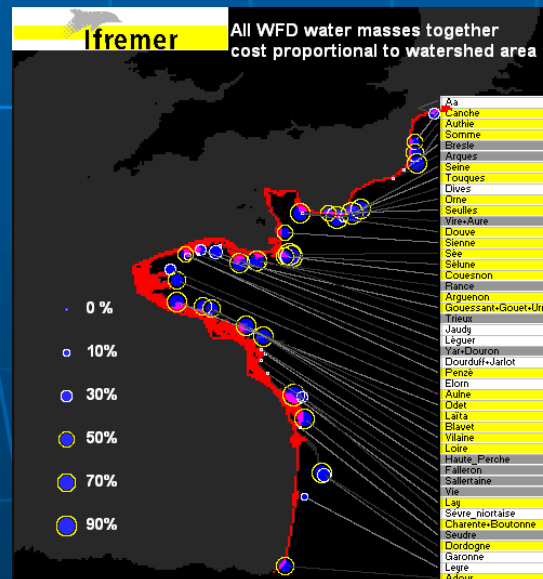

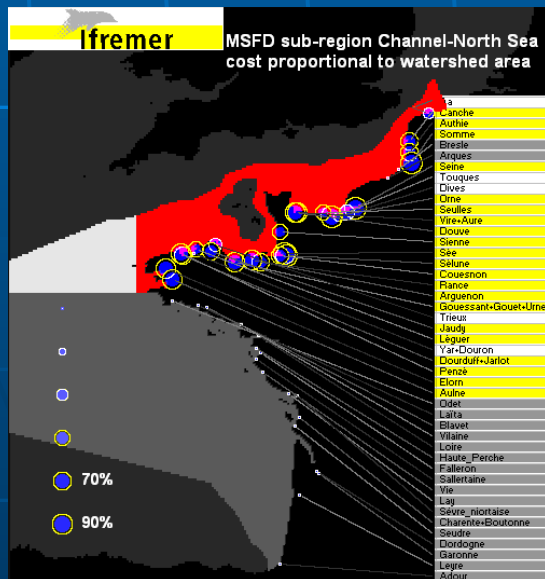

(ONEMA-Ifremer project)

For a single WFD water mass, different rivers may be chosen depending on the cost of nitrate reduction

Extending the target area involves more and more rivers

On-line real-time modelling of risks

On-line previsions on previmer.org website

Basic grid:
the whole coastal waters
off Brittany

Tracking river nitrogen on-line!

Concept : Tracking any evolutive signature in a distributed trophic network

Ménesguen et al., 1997 MEPS ; Ménesguen et al., 2005 Limnol. Oceanogr.

For the biogeochemical state variable B_i , having the signature $S(B_i)$:

- the current mass evolution equation is:

$$dB_i/dt = \text{sources}(B_1, B_2, \dots, B_n, t) - \text{sinks}(B_1, B_2, \dots, B_n, t)$$

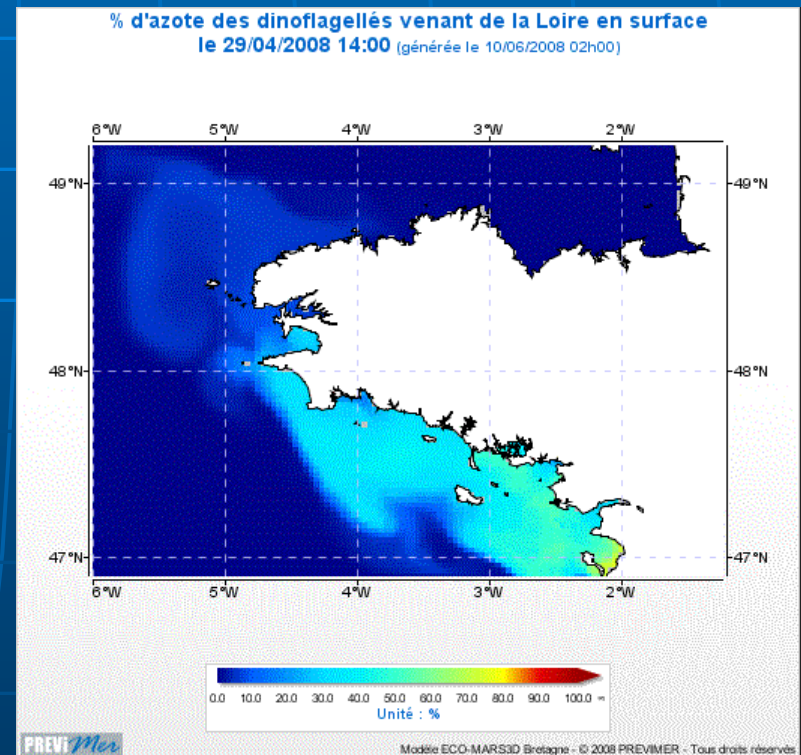

- the new « signed mass » evolution equation is:

$$dB_{s_i}/dt = \text{sources}(B_1, B_2, \dots, B_n, t) \times S(\text{source}) - \text{sinks}(B_1, B_2, \dots, B_n, t) \times S(B_i)$$

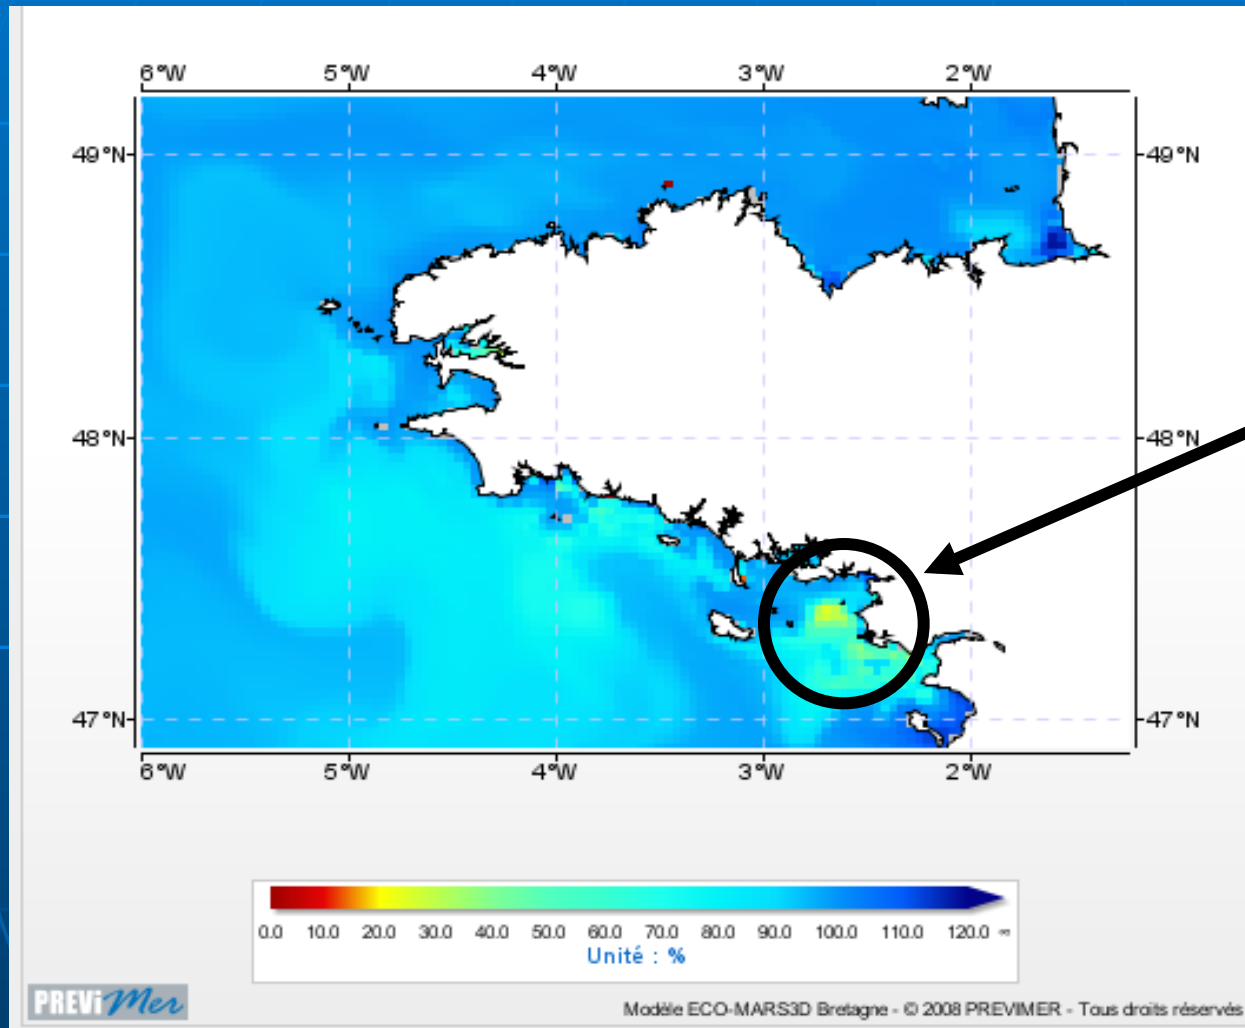

- the signature $S(B_i)$ is:

$$S(B_i) = B_{s_i} / B_i$$

Application : Diatom nitrogen fraction (%) coming from Loire river

Hypoxia alert on July 27th, 2007

Bottom
saturation:
20%

ASP alert on May 12th, 2008

Pseudo-Nitzschia chlorophyll

CONCLUSION

- ❑ Eutrophication of many coastal waters is a multisource phenomenon, that will continue for many years. 3D modelling can help to determine more accurately in space and time the nutrient sources which are the most responsible.
- ❑ Hydrodynamical models can delineate the statistical marine receiving area of any watershed.
- ❑ Eco-hydrodynamical models can track the chemical inputs of any watershed in the global trophic web all over the domain.
- ❑ Nitrogen remains a dominant control variable in marine coastal ecosystems, and scenarios modelling points to 10mg/L NO₃ in river waters as a good target for marine Good Ecological Status
- ❑ Today, results of operational 3D biogeochemical models of the shelf can daily provide on the Internet some eutrophication descriptors: dissolved oxygen, total chlorophyll, toxic species abundance...
